NC: Licensing and Underspecification in Optimality Theory

Junko Itô, Armin Mester, and Jaye Padgett

University of California, Santa Cruz

1 Introduction

It is a common observation that redundant phonological features are mostly inert, neither triggering phonological rules nor interfering with the workings of contrastive features. Consider redundant sonorant voicing vs. distinctive obstruent voicing: In languages enforcing a ban on multiple occurrences of [voice] within certain domains—Japanese, or Proto-Indo-European (in the ‘standard’ reconstruction, see Hayward 1989:45, Garrett 1991:793-803)—this constraint manifests itself in the fact that a voiced obstruent never cooccurs with another voiced obstruent (within the same root). Such voicing constraints leave sonorants unaffected: Although voiced, they freely cooccur with each other and with voiced obstruents; their redundant voicing is apparently invisible to the constraint.

This link between phonological contrastiveness and activity on the one hand and phonological redundancy and inactivity on the other has played a key role in modern phonology. In a variety of recent theoretical approaches (beginning with Kiparsky 1982; see Steriade 1994 for comprehensive references), phonological inactivity has been formally expressed as feature underspecification: unlike voicing in obstruents, voicing in sonorants is literally not specified in the phonology. This underspecification of redundant features holds of underlying representations and persists into the phonological derivation.

There can be little doubt that theories of underspecification, as developed over the last decade (whether ‘radical’, ‘contrastive’ or other), have brought a new depth of explanation to a number of areas of phonological analysis (for example, morpheme structure constraints, harmony systems, assimilation and dissimilation). Building on this notion of underspecification, Lexical Phonology (Kiparsky 1982 et sqq.) developed a principled typology of phonological rules that went far beyond earlier models and found a natural place within a comprehensive view of the phonological grammar as a multi-level derivational system.

While the concept of underspecification has thus played a pivotal role, serious analysts did not fail to note the existence of certain problems and paradoxes threatening the conceptual

and empirical basis of underspecification theory. This point has been made forcefully by McCarthy & Taub (1992) regarding the (under)specification of the feature [coronal] in English consonants (as the default member of the contrastive consonantal place category): Though several arguments for the underspecification of [coronal] have been adduced, based on facts of distribution (Yip 1991, Davis 1991) or assimilation (Avery & Rice 1989), numerous generalizations holding of coronals during the early derivation require reference to [coronal], and hence specification. The generalizations in question hold of the entire class of coronals, including both marked (e.g. [θ,ʃ]) and unmarked members (e.g. [t,s]). Here are two examples (see McCarthy & Taub 1992 for others): (i) all initial 'coronalC+[yu]' sequences are prohibited in American English (*[θyu], *[tyu] (Borowsky 1986); (ii) any OCP-based account of the [ɨ]~∅ alternation found in the plural, possessive, and past tense suffixes in English (*hit*[s], *hide*[z], *kiss*[ɨz], *wish*[ɨz], etc.) must build on the agreement in both place and manner between the consonants in question, and hence presupposes that the feature [coronal] is specified in all coronals (Borowsky 1986, 1987). Though one might entertain some hope that such facts could be accounted for by judiciously ordering default specification of [coronal] between the relevant statements, such attempted ordering solutions are unlikely to have a principled basis, not to mention the difficulty of meeting the simple criterion of descriptive adequacy (ordering paradoxes, etc.).

The coronality problem calls [coronal] (and more broadly, radical) underspecification into question; in fact, it is precisely facts of this kind that have figured prominently in the argumentation for 'contrastive' (or 'restricted') underspecification theory (i.e. underspecification of redundant features, but not of default values of contrastive features, see Steriade 1987, Clements 1987, & Mester & Itô 1989). Further reflection and investigation reveals, however, that the demarcation line between phonologically active features and phonologically inactive features does not fall precisely where contrastive underspecification theory draws it; underspecification paradoxes involving only redundant features are not difficult to find (although they are hardly ever mentioned in the standard literature).

One case of this kind, involving nasals and [voice] in Japanese, was brought forth and discussed in the appendix of Itô & Mester (1986), where the problem lies in the presence of

redundant values in some contexts but not in others. In this paper, we reconsider these facts and show that such underspecification paradoxes are not minor problems, but rather result from an incorrect theory that views phonological constraints as absolute and inviolable wellformedness conditions, relativized in terms of individual grammars (“parameter settings”) and to modules/levels within a grammar (“turning off”). In contrast, Optimality Theory (Prince & Smolensky 1993, see also McCarthy & Prince 1993), which we adopt in this study as a conceptual framework, holds that all phonological constraints are **uniformly present** in all grammars and at all levels, but are in principle **violable** (constraint violation is always minimal, within a grammar consisting of a hierarchy of ranked and violable universal constraints, see section 3 below for a summary). Our general goal is to show how an optimality-theoretic conception of phonology overcomes some of the limitations of the traditional ways of treating redundancy and predictability. We harness optimality-theoretic insights to breathe new life into the use of underspecification. In accordance with the output-oriented framework we adopt, conventional Underspecification Theory in the sense of legislation of feature minimization at underlying and intermediate representations is eschewed. But different from attempts to simply give up on phonological underspecification (and instead appeal to feature proliferation, visibility parametrization, or repair and rescue devices, see Calabrese 1993, Mohanan 1991, Steriade 1994 for various proposals), the theory developed here continues to grant a significant role to phonological underspecification—not as an input property but as an emergent *output* property enforced by feature licensing constraints. Since there is no sequential phonological derivation in Optimality Theory, there is also no sense in which (parts of) the phonological derivation could be characterized by underspecification. The resulting conception diverges significantly from the dichotomy between uniform specification and uniform underspecification that characterized the standard theory. In optimality-theoretic terms, specification or nonspecification of a feature is just one aspect of the selection of the optimal output for any given input by the grammar; this selection depends on the structure of the input, and different results are possible, and indeed expected, for differently structured inputs. Specificational uniformity across all outputs at a certain level is not an operative consideration.

As further goals of the paper, we hope to shed some light on the properties of post-nasal voicing and of rules spreading redundant features in general, develop a notion of *feature*

licensing, and provide insights into the workings of Optimality Theory itself, focussing on issues related to lexicon optimization and constraint family dispersion.

This paper is structured as follows. After a presentation of the nasal voicing problem (section 2), we develop an optimality-theoretic conception of feature licensing, illustrating and motivating it by means of an analysis of Japanese NC voicing (section 3). We turn next to some issues regarding input feature specification and lexicon optimization (section 4) and take up questions related to multiple linking (section 5), developing our analysis along the way. We conclude the paper with a summary of the main results and a discussion of a number of open issues (section 6).

2 The Problem: Voicing and Nasals in Japanese

Japanese exhibits a morphophonemic alternation known as *Rendaku* ('sequential voicing'): under compounding, as in (1), an initial obstruent in the second member becomes voiced (Martin 1952:48-49, McCawley 1968:86-87). The alternation is confined to the Yamato (native) stratum of the lexicon, and, though productive, has lexical exceptions. In the terminology of classical Lexical Phonology (e.g. Kiparsky 1985), *Rendaku* has all the characteristics of an early lexical process.

- (1) a. ori **kami** ⇒ ori+**gami** 'paper folding'
b. oo **sumoo** ⇒ oo+**zumoo** 'grand *sumo* tournament'
c. yama **tera** ⇒ yama+**dera** 'mountain temple'
d. mizu **teppoo** ⇒ mizu+**deppoo** 'water pistol'
e. mizu **hana** ⇒ mizu+**bana** 'running nose'

(h < /p/)

Itô & Mester (1986:71-72) provide an analysis of *Rendaku* as an autosegmental [voice] morpheme which is realized at the left edge of the second member. On this basis, the analysis derives the phonological characteristics of the voicing morpheme from general principles of phonological wellformedness like the Obligatory Contour Principle ("OCP": Leben 1973, McCarthy 1986).¹ The key observation about *Rendaku* concerns its interaction with a constraint on Yamato roots prohibiting more than one voiced obstruent per root (i.e., there are no forms like

dabi*, **gugi*, etc.). This interaction, known as Lyman's Law, manifests itself in the obligatory absence of Rendaku voicing in forms as in (2), where the second member already comes with underlying voiced obstruent. The OCP holding over the [voice] tier provides a unified explanation both for the morpheme-structural fact that there are no roots like **dabi* and for the derivational fact that Rendaku voicing is blocked in *širo-tabi* (širo-dabi*) (see Itô & Mester 1986 for details of the analysis.)

- (2)
- | | | | |
|----|----------------------|--------------------|----------------------------|
| a. | širo+ tabi | ‘white tabi’ | <i>*širo+dabi</i> |
| b. | ore+ kugi | ‘broken nail’ | <i>*ore+gugi</i> |
| c. | mono+šizuka | ‘tranquil’ | <i>*mono+jizuka</i> |
| d. | maru+had daka | ‘completely naked’ | <i>*maru+badaka</i> |

Of special interest here is the fact that sonorants do not behave as voiced for the purposes of Lyman's Law: Neither vowels nor sonorant consonants (see (1)) exert any blocking effect on Rendaku voicing. Examples like (3) make the additional point that voiceless segments are transparent to Lyman's Law: the blocking effect of a voiced obstruent extends across voiceless segments to the left edge of the domain.

- (3)
- | | | | |
|----|---------------------|-------------------|----------------------------|
| a. | onna+ kotoba | ‘feminine speech’ | <i>*onna+gotoba</i> |
| b. | ko+ hitsu ji | ‘child lamb’ | <i>*ko+bitsuji</i> |

Underspecification theory establishes a link between redundancy, unmarkedness, and phonological inactivity. Under any conception, the redundancy of [voice] in sonorants entails the underlying absence of such [voice] specifications. The transparency of voiceless obstruents follows either from the absence of (unmarked) [-voice] in obstruents along the lines of radical underspecification theory (Kiparsky 1982, Archangeli 1984, Itô & Mester 1986, among others) or from the nonexistence of this value in privative voicing theory (Trubetzkoy 1939, Steriade 1987a, Mester & Itô 1989, Cho 1990, Lombardi 1991, among others). The OCP effect over [voice] will therefore obtain as indicated in (4) (we are using ‘V’ to abbreviate [voice] and ‘ \perp ’ to express non-association).

- (4)
- | |
|---------------|
| onna + kotoba |
| \perp |
| V V |

The facts seen so far provide strong support for the underspecification of redundant features (here, [voice] in sonorants). A second constraint holding of Yamato forms illustrated in (5) requires all nasal-obstruent (henceforth: NC) clusters to be voiced throughout.

- (5) a. **tombo** ‘dragonfly’ cf. ***tompo**
 b. **šindo-i** ‘tired’ ***šintoi**
 c. **unzari** ‘disgusted’ ***unsari**
 d. **kaŋgae** ‘thought’ ***kaŋkae**

We state this constraint informally in (6):

- (6) A nasal must share the feature [voice] with a following consonant

Speaking procedurally, nasals spread [voice] to a following obstruent. This holds not only as a morpheme structure constraint, as illustrated in (5), but is instantiated in alternations as well, as seen in examples involving gerundive *-te* in (7).

- (7) a. /yom + te/ ⇒ **yonde** ‘reading’
 b. /šin + te/ ⇒ **šinde** ‘dying’

There is no comparable voicing after other sonorants, neither after vowels (8a) nor after other nonnasal sonorant consonants like *r* (8b,c).²

- (8) a. /mi + te/ ⇒ **mite** ‘seeing’
 b. /tor + te/ ⇒ **totte** ‘taking’
 c. /kaw + te/ ⇒ **katte** ‘buying’

The basic analysis of NC voicing in Itô & Mester (1986:69-71) takes a standard view of such facts (cf. Kiparsky 1982); in brief:

- The redundant [voice] of nasals is underspecified (9a).
- At some point during the phonological derivation, nasals receive [voice] (9b).
- [voice] spreads rightward (9c) by means of a rule independently necessary within the analysis.

(9) NC Voicing:

- | | | | | | |
|----|-------------|----|-----------|----|------------|
| a. | Underlying: | b. | N Voicing | c. | NC Voicing |
| | N C | ⇒ | N C | ⇒ | N C |
| | | | | | / |
| | | | V | | V |

However, Itô & Mester (1986:69-71) also show that these assumptions lead to an underspecification paradox, a point later taken up in Borowsky (1986: 34) and Taub (1988). Nasals (together with other sonorants) must *not* be specified for [voice] when Rendaku and Lyman's Law apply, as seen in (1) above. This implies that Rendaku and Lyman's Law must take place before the assignment of redundant [voice] to nasals (9b). By transitivity, NC voicing (9c), which must follow (9b), should also not be visible to Lyman's Law. However, the facts show the opposite: NC voicing *is* visible to Lyman's Law and blocks Rendaku, as illustrated by compounds like *širooto-kaŋgae* 'layman's idea' (10) (**širooto-gaŋgae*).

(10) The underspecification paradox for serial derivations:

haya-gane 'fire bell' vs. *širooto-kaŋgae* 'layman's idea'

a.	Underlying:	/haya+kane/	/širooto+kaŋkae/
	Rendaku:	haya+ gane	širooto+ gaŋkae
	N&NC Voicing:	haya+gane	širooto+ga ŋgae
	Output:	✓ haya+gane	*širooto+gaŋgae
b.	Underlying:	/haya+kane/	/širooto+kaŋkae/
	N&NC Voicing:	haya+kane	širooto+ka ŋgae
	Rendaku:	(blocked by OCP)	(blocked by OCP)
	Output:	*haya+kane	✓ širooto+kaŋgae

The derivations in (10) bring out the contradiction by contrasting a form with a plain medial nasal, which requires Rendaku to precede N-Voicing (10a), with a form containing a medial NC cluster, which requires the opposite order (10b). We have, then, a paradox: Nasals in NC clusters must be specified for [voice] just when other nasals must not be. A blanket approach invoking a redundancy rule [+nasal] → [+voice], whether by stipulation to a domain or by the Redundancy Rule Ordering Constraint (Archangeli 1984, Archangeli & Pulleyblank 1986), fails because it paints with too wide a brush, requiring that *all* nasals receive [voice], if any do. Instead, nasals appear to receive [voice] only where necessary to trigger NC voicing. We

could of course encode this fact in the redundancy rule itself, by making the presence of a following obstruent a condition on the insertion of [voice]. Such a solution is little more than a statement of the problem, since it remains a coincidence that insertion takes place just in the context where another rule will later apply to spread [voice] onto the following consonant. (Why not insert [voice] on final nasals? Or on nasals before high vowels? etc.) As a minimal condition of adequacy, we require that the analysis attempt to establish some relation between the NC voicing phenomenon and the presence of redundant [voice] in N.

In response to this problem, Itô & Mester 1986 propose a level-ordered solution, in which nasal voicing is inserted at a level prior to other sonorant voicing, noting at the same time that this proposal, although descriptively adequate, has serious drawbacks and in any case cannot serve as a general answer to underspecification paradoxes. An interesting new idea appears in Borowsky (1986: 34), relying on an unorthodox assumption about the feature structure of linked NC-clusters. Although the account succeeds in deriving the postnasal voicing facts without additional machinery, Taub's (1988: 70–73) comprehensive discussion shows that the paradox itself still remains. However, one of the central ingredients of Borowsky's account—the idea to relate postnasal voicing to segment markedness conditions (nasals must be voiced, and obstruents can accommodate voicing)—is preserved, albeit in a different form, in our optimality-theoretic account below. Other proposals have tried to circumvent the paradox by spitting the distinctive feature [voice] into several subfeatures which can be separately appealed to (see Rice 1993 for [spontaneous voicing], Steriade 1994 for [expanded pharynx]). But precisely because such analyses differentiate in a fundamental way between sonorant and obstruent voicing, voicing *interactions* between the two segment classes, as in NC voicing, come as an unpleasant surprise, to be accommodated by special pleading (see section 6 for further discussion). We will argue that the trouble lies not with [voice], but with the traditional view of the organization of phonology; and the challenge is to resolve the paradox without destroying the unity and integrity of the distinctive feature [voice].

Taking a fresh look at the problem, the solution to be developed builds on an understanding of redundant feature (under)specification in terms of *licensing*, advanced in the setting of Optimality Theory. This solution, while conceptually very different and with somewhat different empirical consequences, shares one crucial point with the earlier analysis of Itô &

Mester 1986: It relies on the fact that within specific grammars, general constraints can be decomposed into a *family* of separate more specific conditions: Nasal voicing can be separated from other sonorant voicing (cf. the similar decomposition of [ATR]/height constraints for vowels in Archangeli & Pulleyblank in press), employing a notion of what we will refer to as *constraint family dispersion* (first proposed in Prince & Smolensky 1993, henceforth PS 1993).

3 Feature Licensing and Redundancy

3.1 Optimality-theoretic Background

The basic tenets of Optimality Theory which will be important to our theory of feature licensing are constraint-based output selection, constraint universality and ranking, and the principle of minimal violation (see PS 1993 for a comprehensive and more formal presentation, as well as McCarthy & Prince 1993, 1994 and references therein for further details).

[i] *Constraint-based output selection:* The output of phonology or morphology is determined by wellformedness constraints that select among some candidate set of forms (based on some underlying representation as input), considered in parallel. As a result, there are no rules or repair strategies, and no serial derivation. Candidate sets are in principle infinite and maximally inclusive, leaving the job of winnowing out forms to the wellformedness constraints.

[ii] *Universality and ranking:* The set of constraints \mathbb{C} is provided by Universal Grammar ($\mathbb{C} = \{C_1, C_2, \dots, C_n\}$); an individual grammar \mathbf{G} is obtained by imposing a strict dominance order \gg on the elements of \mathbb{C} ($\mathbf{G} = (\mathbb{C}; \gg)$). In the standard conception, the relation \gg is a strict linear order, i.e. it is total, transitive, and asymmetric: for any two constraints C_i and C_j , either $C_i \gg C_j$ or $C_j \gg C_i$, but not both; and if $C_i \gg C_j$ and $C_j \gg C_k$, then $C_i \gg C_k$.³ The wellformedness constraints in \mathbb{C} form the substance of some part of theoretical phonology, e.g. prosodic phonology, feature geometry, the theory of autosegmental operations, etc.

[iii] *Minimal violation:* All constraints are in principle violable. Ranking and violability are the key characteristics of Optimality Theory that set it apart from other conceptions of grammar (like the minimalist program outlined for syntax in Chomsky 1993). In particular, these concepts are not found in other non-derivational constraint-based theories of phonology, such as Harmonic Phonology (Goldsmith 1990, 1991, 1992) and Declarative Phonology (Scobbie 1991) (though cf.

Paradis 1988a,b for a different kind of constraint violability and constraint ranking in derivational terms, see PS 1993: 214–219 for discussion). And arguably these two properties of ranking and violability are the crucial elements responsible for the theory's explanatory successes, not only in phonology, but also in other areas of grammar, including prosodic morphology (McCarthy & Prince 1993), allomorphy (Mester 1994) and syntax (Grimshaw, to appear).

The output of an optimality-theoretic grammar, as noted, is not the result of a derivation, as in standard phonological theorizing. Rather, phonological adjudicating proceeds in parallel: every possible candidate is considered for a given input form.⁴ The actual output form—the optimal form—is the (often, but not necessarily, unique) member of the candidate set that best-satisfies the constraint hierarchy. We will see in the next section, with concrete examples, how ‘best-satisfaction’ can be determined in a straightforward way for tableau representations of candidate sets (see PS 1993:68-76 for a formal definition in terms of HARMONIC ORDERING).

This sketch of Optimality Theory (OT) is incomplete in various respects, but sufficient to set forth our basic hypotheses about redundancy and underspecification, which is intrinsically linked to a conception of constraints as ranked and violable. Our goal is to explain the specificational behavior of redundant features (like [voice] in nasals) as the result of the antagonistic interaction of two families of constraints, one favoring richness of phonetic specifications, the other one favoring the opposite. Both groups of constraints are part of the dominance hierarchy that constitutes the grammar of a language.

On the one hand, there are the familiar phonetic-realizational constraints (involving ‘grounding’, in the terminology of Archangeli & Pulleyblank in press), where representations are required to be richly specified for phonetically required or desirable properties. These include the redundant properties for each segment class; they may be physically inherent, or serve to enhance contrasts, or in other ways be favored (see Stevens, Keyser & Kawasaki 1986). Thus, sonorants are voiced, back (nonlow) vowels are round, high vowels are [+ATR], etc.

On the other hand, there is the world of feature minimization and distinctiveness: languages are inventory-wise parsimonious, building on a few operative phonetic distinctions. The many other distinctions that form part of the spectrum of universal phonetic capabilities of humans play no role in the organization of the inventory.

These two factors—one favoring specificational abundance, the other one favoring specificational parsimony—are antagonistic. Standard underspecification theories, with their apparatus of feature minimization, marking conventions, default and redundancy rules, orderings, etc., can be viewed as particular ways of adjudicating between them. Faced with antagonistic principles, a theory subscribing to the view that grammatical constraints are always inviolable at their point of application only has the option of assigning the two antagonistic principles different parts of the derivation (early vs. late) as their respective domains, such that each of them can hold true within its particular domain. It is this attempt to find the solution in derivational differentiation that leads straight into underspecification paradoxes.

Optimality Theory, on the other hand, can adjudicate between the two kinds of constraints by ranking them directly with respect to each other, without having to create a special derivational stage or level during which redundant features are absolutely prohibited. A crucial aspect of our solution to the feature specification problem is that it builds on a small group of simple constraints, all independently motivated and plausible candidates for Universal Grammar.

3.2 Underspecification as an Output Property

Consider the connection, often merely implicit in practice and yet clear in principle, between feature redundancy and feature underspecification. Building on a proposal made in Padgett (1991:56-8), we link the two by means of the notion of *licensing*. The hypothesis formulated in (11), as a principle of universal grammar, is an explicit statement of this connection (cf. the redundancy rules and marking conditions of Kiparsky 1985, Archangeli & Pulleyblank 1986, and others).

(11) Licensing Cancellation: If $\mathbf{F} \supset \mathbf{G}$, then $\neg(\mathbf{F} \lambda \mathbf{G})$.

"If the specification \mathbf{F} implies the specification \mathbf{G} , then it is not the case that \mathbf{F} licenses \mathbf{G} ."

The statement in (11) is intended as follows: Suppose a grammar contains a segment structure condition expressing the segment-internal redundancy that a segment that has the feature \mathbf{F} also has the feature \mathbf{G} . Then the feature \mathbf{G} is not licensed within a segment containing \mathbf{F} . For example, given the redundancy implication $[\text{son}] \supset [\text{voice}]$, a sonorant segment does not license

Thus, a redundancy implication $[\text{son}] \supset [\text{voice}]$, given Licensing Cancellation, means that the feature $[\text{voice}]$ is not licensed in a sonorant segment (12b). The absence of $[\text{voice}]$ is forced by the relevant member of the family of feature licensing constraints schematically characterized in (14).

(14) License(Φ): The phonological feature Φ must be licensed.

In the context of our discussion, the relevant redundancy implication in Japanese (shared by all natural languages) is the one repeated in (15) (we follow the convention in OT of abbreviating constraint names for use in constraint tableaux). This condition in fact represents a whole family of sonorant voicing conditions (governing nasals, liquids, vocoids, and other sonorants).

(15) SONVOI $[\text{son}] \supset [\text{voice}]$

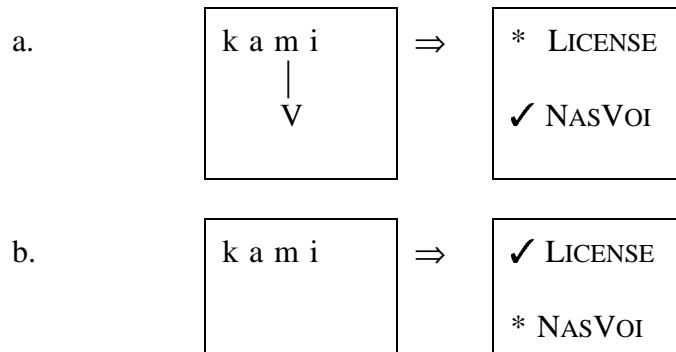

To illustrate the role of feature licensing in our account of Japanese, consider an example like *kami* ‘paper’. The relevant members of the constraint families involved are the voice-licensing constraint LICENSE(VOICE) (16), where $\Phi = [\text{voice}]$, and the nasal version of the sonorant voicing condition NASVOI (17).

(16) LICENSE(VOICE) I.e., the feature $[\text{voice}]$ must be licensed.

(17) NASVOI I.e., $[\text{nasal}] \supset [\text{voice}]$

Since LICENSE(VOICE) is the only member of the family of Licensing constraints to play a role in our analysis, we will refer to this constraint simply as LICENSE. Focussing on the nasal $[\text{m}]$ in *kami*, we have two potential candidate representations: one with the nasal specified for voicing (18a), and one with the nasal unspecified (18b).

(18)

(18a) fulfills NASVOI, but violates LICENSE. (18b), on the other hand, violates NASVOI, but fulfills LICENSE. The situation thus looks like a stand-off, with each representation incurring one constraint violation, while fulfilling the other constraint. This is the kind of constraint conflict that Optimality Theory resolves, with its notion of constraint domination (see the earlier discussion in section 3.1). Leaving details to the more technical expositions of the formal theory (see especially PS 1993), the central idea is that constraints are ranked in a strict domination order, with higher constraints taking absolute precedence over lower constraints. For the case at hand, we hypothesize that the condition LICENSE is ranked above the voicing condition NASVOI. In the notation of OT, this is written as in (19).

(19) LICENSE >> NASVOI

Given this constraint ranking, (18b) is the winning candidate, with the nasal unspecified for voicing. The OT-style tableau, which illustrates the crucial ranking graphically in terms of columns ordered from left to right, is given in (20).

(20)

	Candidate	LICENSE	NASVOI
a. 	k a m i		*
b.	k a m i v	*!	

In tableaux, a ‘*’ in row *i*, column *j* indicates that candidate *i* violates constraint *j*. Candidate (20b), for example, violates LICENSE. Evaluation of the candidates proceeds recursively by constraint, until all candidates besides the winning candidate are eliminated. In this simple case, the decision is already reached in the first round. ‘*!’ denotes the crucial failure of a given candidate. Here is the sense in which there are no trade-offs: even the most splendid fulfillment of subordinate constraints cannot rescue a candidate that has slipped with respect to a higher-ranking constraint in the eyes of the theory. In this way, the winning candidate emerges as optimal, a status denoted by the pointing hand (). The optimal candidate is the only wellformed candidate, and is selected as the output. All other candidates are illformed. Though violations after critical decision points are recorded for completeness, these results have no bearing on the outcome, a fact indicated by shading of the corresponding cells.

The constraint configuration in (20) is the core of our proposal in this paper, which will be further fleshed out in crucial respects as we proceed. In general (with one important exception, to be discussed below), it settles exactly on the degree of feature (under)specification amply supported in past work on Japanese Phonology and elsewhere. More concretely, (20a) is the empirically justified underspecified representation for Rendaku and Lyman's Law, as we have seen: [m] does not carry [voice], hence Rendaku voicing is not blocked and applies to the initial [k] in (21a).

- (21) a. ori kami ⇒ ori+gami, *ori+kami ‘folding paper’
b. nise kagi ⇒ *nise+gagi, nise+kagi ‘fake key’
c. ao kaki ⇒ ao+gaki, *ao+kaki ‘green persimmon’

In contrast, a form like *kagi* ‘key’ (21b), with distinctive voicing on /g/, does not have the unspecified representation. The fact that [voice] is distinctive for obstruents means that there cannot be a redundancy condition for obstruent voicing (since the unpredictable cannot be predicted). Consequently, Licensing Cancellation does not take effect, and the voicing on the medial /g/ fulfills LICENSE (22a). NASVOI is vacuously satisfied since the form has no nasal segment. The voicing feature licensed by the medial obstruent [g] manifests itself by blocking Rendaku voicing in (21b). The medial obstruent in *kaki* ‘persimmon’ (21c) likewise satisfies LICENSE and NASVOI (22b).

(22)

- a.

k a g i V

 ⇒

✓ LICENSE
✓ NASVOI
- b.

k a k i

 ⇒

✓ LICENSE
✓ NASVOI

Turning now to the post-nasal voicing facts presented in section 2, we have to account for the fact that there are (Yamato Japanese) roots like *tombo* ‘dragon fly’, but no roots like **tompo*, and for alternations like /yom + te/ → *yonde*, not **yonte*. Focussing on the NC-cluster (and abstracting away from place assimilation), consider first the following two candidates that are parallel to (18):

(23)

- a.

t o m p o V

 ⇒

* LICENSE
✓ NASVOI
- b.

t o m p o

 ⇒

✓ LICENSE
* NASVOI

Everything else being equal, the same reasoning applied for (18) should lead to the conclusion that (23b) is superior. Not everything is equal, though, since in this case there is another relevant candidate (24), with doubly linked voicing.

(24)

The feature [voice], though not licensed by the nasal root node, is here licensed by the obstruent root node, and hence fulfills LICENSE. This last candidate representation, which fulfills both Voice Licensing and the redundancy condition that nasals should be voiced, is therefore superior to both of the representations in (23), each of which respects only one of the conditions. This is more perspicuously brought out in tableau (25).

(25)

Recall in what respect feature licensing differs from statements like *[nasal, voice]: in our terms, the nasal segment is in no sense incompatible with linked [voice]. Rather, it merely fails to grant licensing; such licensing however is conferred by the obstruent root node. Feature licensing explains why only doubly linked NC nasals are (redundantly) voiced. In its crucial rejection of the notion that a voicing condition like NASVOI is no force at all at some early 'level' of the phonology, this picture of underspecification is specific to an account in the spirit of OT.

In the absence of evidence to the contrary, we assume that LICENSE is undominated. Given the possibility envisioned within OT of deriving new grammars by reranking constraints, we might expect to find some language with the ranking NASVOI >> LICENSE, which entails redundant [voice] specification. (We might similarly find such a ranking between any redundancy condition and the related licensing condition, in Japanese or elsewhere). However, the issue is complicated by an evident need for a theory of *ranking markedness* itself, given the existence of apparently robustly undominated constraints across languages (see e.g. PS 1993 and McCarthy & Prince 1993).⁵

The result of the considerations in this section is that feature spreading configurations are advantageous: Clusters doubly linked for [voice], such as Yamato Japanese NC clusters, are optimal because they simultaneously fulfill both constraints—feature licensing and the nasal voicing condition. Everything else being equal, no representation fulfilling only one of these constraints while violating the other one could be superior.

But — is everything else truly equal? What is the cost exacted by feature spreading itself, compared to representations without the extra associations? In most rule-based theories of phonology, feature spreading is ascribed to the operation of a phonological rule, spreading is not 'automatic' (see Pulleyblank 1986 for an extended argument to this effect). It seems reasonable to hypothesize, then, that multiply linked configurations must exact some price. How should the extra association lines be counted, and how should these marks be weighed against the marks incurred for other constraints?

Such questions are important not just for the particular analysis being pursued here, but for a proper understanding of Optimality Theory itself as a general theory of phonology extending beyond prosodic phonology (syllable and foot parsing, etc.) into the area of (auto)segmental phenomena, where spreading and delinking have figured very prominently in past analyses. Seeking an answer to these questions, the next section develops the standard theory of faithfulness constraints and explicates the nature of inputs in a theory that adopts a principle of lexicon optimization (PS 1993).

4 Input-Output Disparities: Faithfulness and Lexicon Optimization

In Optimality Theory, much of the role of the traditional phonological derivation, as a sequence of operations modifying inputs in a step-by-step fashion, is taken over by the Generator (Gen). Roughly speaking, the results of phonological operations are included in the vast class of 'improvisations' that Gen produces for a given input as the associated candidate set, which is then evaluated by the constraint hierarchy of a particular grammar. Central to an enterprise of this kind are constraints that regulate input/output disparities. This role falls to the constraints PARSE and FILL introduced in PS 1993, known collectively as the FAITHFULNESS family of constraints.

Faithfulness favors minimal deviation: PARSE militates against underparsing ('deletion': a failure to parse an input element in the output), whereas FILL militates against overparsing ('insertion', a failure to fill a phonological position with underlying material, i.e. the appearance of output elements which are not part of the input).⁶ Since we are here concerned with elements at the featural level (and not just with whole segments) and with association relations between elements of feature structure, it is incumbent upon us to address the issue of Faithfulness in a more general way. Faithfulness, understood as a ban on disparities between input and output, must cover both substance and structure. Besides macro-elements like whole segments, Faithfulness governs individual features as well as *association relations* between features.

Building on PS 1993 and on our earlier optimality-theoretic work (Itô, Mester, & Padgett 1993), as well as that of others (McCarthy & Prince 1993, Myers 1993, Archangeli & Pulleyblank 1993),⁷ we extend the Faithfulness constraints as in (26). Since the individual constraints shown below need not be distinguished in the ranking hierarchy to be discussed, we group the family of Faithfulness constraints into a single collective constraint FAITH.

(26) **FAITH** (Feature Faithfulness)

- | | |
|------------|--------------------------------------------------|
| PARSEFEAT: | All input features are parsed. |
| FILLFEAT: | All features are part of the input. |
| PARSELINK: | All input association relations are kept. |
| FILLLINK: | All association relations are part of the input. |

Gen can insert new structure/features, and fail to parse input structure/features, at the price of accruing FAITH violations. These constraints assign the cost corresponding to an appeal to

autosegmental operations like spreading, insertion or deletion in a rule-based derivational analysis.

We will presently see that FAITH is dominated by LICENSE and NASVOI: As a consequence, FAITH is violated under the pressure to fulfill one of these higher-ranking constraints. First let us see a more elementary role for FAITH: this constraint militates against the sheer gratuitous insertion or deletion of a feature like [voice].

Consider first the form /kaki/ ‘persimmon’ in (27), with two underlyingly voiceless obstruents. As members of the candidate set associated with this input, Gen submits the representations in (27), with and without inserted [voice]. (Here and throughout, inserted elements are bolded. The dashed line in the tableau indicates that there is no constraint ranking argument regarding FAITH so far.)

(27) Input:

/kaki/		LICENSE	NASVOI	FAITH
a. k a k i				
b. g a k i v				*!
c. k a g i v				*!
d. g a g i v v				*!*

All candidates fulfill the licensing condition and the redundancy condition (see (22) above); and the candidate (27a) that is faithful to the input wins.⁸ In addition to the constraints depicted here, candidate (27d) with two inserted [voice], violates the OCP over [voice] (see section 2). On the other hand, given underlying /kagi/ ‘key’, the candidate (28a) with a *voiceless* medial obstruent, is unfaithful, since it has left the underlying [voice] feature unparsed (indicated by crossing out).

(28) Input:

	LICENSE	NASVOI	FAITH
a. k a k i V			*!
b. ☞ k a g i V			

Thus all else being equal, FAITH makes the choice in favor of the candidate which remains faithful to the input.

Let us now return to forms like *kami* ‘paper’. Assuming an input in which the nasal is unspecified for [voice], FAITH would seem to interact in no interesting way with our analysis, as (29) suggests. Underspecified /m/ again emerges as the winner; the voice-specified candidate only looks worse for the pointless insertion of unlicensed [voice].

(29) Input:

	LICENSE	NASVOI	FAITH
a. ☞ k a m i		*	
b. k a m i V	*!		*

FAITHFULNESS considerations become more interesting, however, when we take into account alternative *input* representations. Suppose that the nasal is specified for [voice] *underlyingly*, as in (30). For this input to surface with [voice] unspecified, as required for Japanese (as evidenced by the Rendaku / Lyman's Law evidence in section 2, cf. *ori-gami*, etc.) [voice] must go *unparsed*, in violation of FAITH. This output, unfaithful to the input, is ensured provided FAITH is outranked by LICENSE.

(30) Input:

	LICENSE	NASVOI	FAITH
a. k a m i V		*	*
b. k a m i V	*!		

Traditional underspecificationist thinking, with its input-focussed feature minimization program, might be baffled at the idea of even considering the possibility of input representations as in (30). But within Optimality Theory, this kind of legislation on inputs has no direct counterpart, and one is compelled to ask what, if anything, governs the degree of specification in input representations. The notion ‘underlying representation’ takes on a somewhat new status in a theory in which the output is determined by the parallel consideration of (potentially limitless) candidate sets (see PS 1993:175-196). Central to the optimality-theoretic enterprise is the hypothesis that explanation can be achieved through output constraints *alone*. Therefore, neither underspecification, nor anything else, can be meaningfully required of inputs (in any case, not directly; see PS 1993:49-51 for further discussion on MPARSE).

The strongest, and therefore most interesting, hypothesis is that output-focussed constraints are not only necessary, but also sufficient. This means that the grammar contains no separate constraint system governing inputs which could enforce a particular degree of (under)specification. Rather, in every case the output constraint hierarchy itself must be able to force the correct outcome, irrespective of the degree of input (under)specification.⁹ Other views are certainly possible, but in the absence of any evidence warranting a more complex theory with an additional level of input constraints, the stronger hypothesis must be maintained. In our terms, underspecification effects are output effects and depend solely on the ranking LICENSE >> FAITH. Underspecification, then, is an *emergent property of the output*. Whether redundant voicing is underlyingly present (30) or not (29), the outputs converge on the same *output core* (parsed

substructure), with /m/ not linked to voice. (This argument is modelled on the approach to segment inventories in PS 1993:178-185).

Consider now the constraint tableau in (31), which evaluates candidates built on the input /tompō/ (for the Japanese form *tombo* ‘dragon fly’). As noted earlier, we assume the candidate set to include any autosegmental ‘improvisation’ on the input—insertion and nonparsing of features, etc. Since our focus is on the medial NC cluster and the feature [voice], we indicate only the presence or absence of relevant voicing specifications in the input and in the candidate forms.

(31) Input:

/tompō/		LICENSE	NASVOI	FAITH
a.	t o m p o		*!	
b.	t o m p o ↓ v	*!		*
c.	t o m b o ↓ v		*!	*
d.	t o m b o ↓ v			**
e.	t o m b o ↓ ↓ v v	*!		**

The two candidates (31b,e) fail for now familiar reasons, falling victim to LICENSE. Candidates (31a,c) are eliminated by NASVOI. The doubly linked candidate (31d) emerges as optimal—though violating faithfulness—since it satisfies both higher ranked constraints. Here we see the crucial ranking of NASVOI >> FAITH: Were this ranking reversed, the faithful candidate (31a) (having passed licensing) would emerge the winner. Instead dominant NASVOI forces the insertion of [voice] and double linking, resulting in multiple violations of FAITH. Thus, post-nasal

voicing depends on the assumption that inserting and spreading [voice] costs less than violating the requirement that nasals be voiced.

Turning now to the question of *input* representations, we will use the same example and consider several alternative input representations for the Japanese form *tombo*. As potential alternative inputs, we choose the five representations in (32) identical with the *output candidates* in (31a-e). Anticipating the main result, we will see that all of these possible inputs converge on an output core with double linking of [voice].

- (32) a. b. c. d. e.
- tampo tampo tombo tombo tombo
- | | ∨ ||
- v v v vv

We have already evaluated the candidate set associated with input (32a) in tableau (31) above. Below we establish that double linking for [voice] is the fate of all the other inputs as well. This result follows from the fact that FAITH is outranked by both LICENSE and NASVOI. These latter constraints will always conspire in the way we have seen to effect double linking, regardless of the amount of feature insertion or nonparsing required. Thus in the following tableau for input (32b), FAITH tolerates the insertion of another association line on the optimal candidate (33d). The faithful candidate (33b), on the other hand, fatally violates LICENSE.

(33)

Input:

	Candidate	LICENSE	NASVOI	FAITH
a.	t o m p o + V		*!	*
b.	t o m p o ↓ V	*!		
c.	t o m b o + V V		*!	**
d. 	t o m b o ↓/ V			*
e.	t o m b o ↓ V V	*!		*

In tableau (34) (for input (32c)) the establishment of a new association line is similarly required in (34d). In this case, the faithful candidate (34c) incurs a fatal violation of NASVOI.

In the next tableau (for input (32d)) we see a happy meeting of the needs of all of our constraints at once: in addition to fulfilling both LICENSE and NASVOI, the optimal form (35d) is also devoutly faithful to the input, a fact that will become significant in our discussion of lexicon optimization below.

(35)

This experiment with various possible inputs bears out our earlier claim that there is no need for a separate theory of underlying feature minimization: The constraint hierarchy itself forces the correct output, irrespective of specification in the input. This means that there is no *grammatical* imperative against even a redundantly specified input form as in (35) or (30) above.

However, there may well be *learnability* factors restricting the choice of the underlying form, requiring that the proper underlying representation be inferable, as the 'simplest' choice, from the constraint hierarchy. The language learner has at his/her disposal the strategy of Lexicon Optimization ('Stampean occultation'; see PS 1993:192, 196 for a full statement):

(37) Lexicon Optimization:

Of several potential inputs whose outputs all converge on the same phonetic form, choose as the real input the one whose output is the most harmonic.

In order to develop these somewhat abstract considerations into a concrete analytical method, we propose the ‘tableau des tableaux’ technique in (38). Taking up a remark in PS (1993, 192), we compare each of the winning outputs seen above for harmonic status, each in relation to the corresponding input. The tableau des tableaux (38) assembles the input-output pairings established in the tableaux (31)–(36), with the set of violation marks for each constraint. All of the winning outputs are doubly linked for [voice], satisfying both LICENSE and NASVOI; they differ only in violations of low-ranked FAITH. As shown, the ‘superhand’ chooses (38d) as the optimal input (i.e., the input associated with the most harmonic of the different outputs).

(38) Tableau des tableaux: evaluating outputs of the different inputs

	Input	Output	LICENSE	NASVOI	FAITH
a.	/tompo/	 t o m b o ∨ V			* ! *
b.	/tompo/ ∨ V	 t o m b o ∨ V			* !
c.	/tombo/ ∨ V	 t o m b o ∨ V			* !
d.	/tombo/ ∨ V	 t o m b o ∨ V			
e.	/tombo/ ∥ VV	 t o m b o ∨ V ∧ V			* ! *

With Lexicon Optimization and tableau des tableaux as a guideline, the learner chooses the input form that maps onto an output in the way least offensive to the grammar of ranked constraints. For our purposes, this means that the learner will choose the input leading to the fewest faithfulness violations, to wit, the input bearing double linking of redundant [voice]. This conclusion, if correct, points up even more dramatically our basic conclusion: there is no requirement of underlying feature minimization.

To recapitulate this section and the overall analysis, we rely on three broad categories of constraints—redundancy conditions, derivative licensing restrictions, and constraints against

input/output disparities. Each of these is largely akin to notions widely held in modern phonology. Our approach to underspecification is novel in two important respects, however. First, our interpretation of licensing puts no penalty on feature cooccurrence per se; rather, a feature is merely required to be licensed in *some* fashion. Second, we rely crucially on the ranking and violability of constraints, notions that form the backbone of Optimality Theory.

Continuing in this last vein, it may seem odd, even in the context of OT, to propose simultaneous constraints, one *demanding* that nasals be voiced (NASVOI), and the other *blocking* licensing of [voice] by nasal segments (LICENSE). Yet as noted at the outset of this section, these are just familiar notions in a new guise, and they must be regarded as two sides of a coin: the import of NASVOI is that voicing is in a sense *inherent* in nasals (Stevens, Keyser & Kawasaki 1986). Yet it is surely the very redundancy of such voicing that also entails its phonological inertness. While the antagonism between these two constraints has led past theories to assign them to complementary 'levels' of the grammar (i.e. underspecification early and presence of redundant values late), we find a new possibility within OT: redundant specification is not simply irrelevant until 'late' in the derivation, but rather is crucially a constant demand. The facts of Japanese provide striking support for this view.

5 Sonorant Voicing and Multiple Linking Conditions

5.1 The problem

A small step back from Yamato NC clusters reveals some highly relevant questions lurking nearby. Our analysis has so far not addressed an important limitation of the process: It is only nasal sonorants that trigger voicing on following obstruents (/yom+te/ → *yonde* 'reading' (**yonte*), but /mi+te/ → *mite* 'seeing' (**mide*)). In singling out nasals from all sonorants as voicing triggers, Yamato Japanese is following a pattern paralleled in other languages, including Zoque (Penutian; Wonderly 1951), Mwera (Bantu; Harries 1950, Kenstowicz and Kisseberth 1977), among others. While comforting, such crosslinguistic support is not enough to answer certain questions of a more fundamental nature:

(i) Nonuniversality of NC voicing: Why don't we find post-nasal voicing in all languages, including English (*impossible*, **impossible*)? Even within Japanese, NC voicing is restricted to

the native (Yamato) stratum (as witnessed by wellknown non-Yamato examples like *tempura* or *shinkansen*).

(ii) Nasals as privileged voicing triggers: If voicing spread takes place in order to allow for the presence of redundant voicing (by finding a licenser), why should this be restricted to nasals? Why don't non-nasal sonorants, say vowels, spread their redundant [voice] in a parallel way?

To illustrate the second question, consider the consequences of replacing the redundancy condition NASVOI in our current analysis by the more general SONVOI (39) requiring all sonorants, not just nasals, to be voiced.

(39) SONVOI: [son] \supset [voice]

SONVOI expresses a general truth about segment structure, and is operative within the constraint system of all languages, including Japanese. For an input like /aki/ (for *aki* 'autumn'), replacing NASVOI by SONVOI in the analysis results in the incorrect multiply-linked output **agi*, shown in (40d). More generally, *all* sonorants are wrongly predicted to cause voicing in neighbouring obstruents.

(40)

Input: /aki/ 'autumn'

Candidate	LICENSE	SONVOI	FAITH
a. !! intended winner: a k i		*!*	
b. a k i ↓ ↓ v v	*!*		**
c. a g i ↓ v		*!*	*
d. a g i ↓ ↓ v		*!	**
e. ✘ wrong winner: a g i ↓ ↓ ↓ v			***

As we will see, the two questions posed above (restriction to nasals and non-universality) are closely related; both will require appeal to constraints on the multiple linking of features.

5.2 A Non-viable Approach: SONVOI Decomposition

One potential solution, attractive at first sight but ultimately not workable, relies on the decomposition of SONVOI into a universally ranked family of sonorant voicing conditions, as in (41) (see Itô, Mester & Padgett 1993 for a detailed exposition of this kind of approach).

(41) Sonorant Voicing Conditions and Conjectured Ranking:

NASVOI: [+nasal] \supset [voice]

APPROXVOI: [+approximant] \supset [voice]

VOCVOI: [-consonantal] \supset [voice]

NASVOI \gg APPROXVOI \gg VOCVOI

The notion of a family of constraints with intrinsic ranking is one of the central analytical tools of Optimality Theory. The individual members of a family of constraints stand in particular dominance relations with respect to each other (given universally), but need not all be adjacent in the constraint ranking of a particular language (cf. PS 1993 on syllable sonority). The possibility that other constraints—most importantly, members of the FAITHFULNESS family—might intervene at certain junctures in the overall hierarchy constitutes an important area of variation between phonologies.

For the case at hand, the most direct attack on the problem of distinguishing nasal voicing from other sonorant voicing is to rank FAITH strategically between NASVOI and APPROXVOI/VOCVOI, as in (42).

$$(42) \text{ NASVOI} \gg \text{FAITH} \gg \text{APPROXVOI} \gg \text{VOCVOI}$$

The occurrence of post-nasal voicing follows from the dominance of NASVOI over FAITH, which is hence violated in order to ensure compliance with NASVOI. Other sonorant redundancy conditions are ranked below FAITH and cannot command violations of it. This ranking yields the correct optimal output for *aki*, as shown in (43). (For our discussion here and below, the distinction between APPROXVOI and VOCVOI is not relevant, and we will simplify the presentation by restricting our attention to the latter.)

(43)

Input: /aki/ 'autumn'

	Candidate	LICENSE	NASVOI	FAITH	VOCVOI
a.	a k i				**
b.	a k i ↓ ↓ v v	*!*		**	
c.	a g i \ / v			*!***	

Insertion of vocalic [voice], and the sharing of this feature with a licenser, as in (43c), is no longer possible; in spite of the condition demanding that vowels be voiced, the dominant position of FAITH entails that the optimal form is unspecified.¹⁰

Though the decomposition of SONVOI into these more particular conditions has no clear independent support within Japanese phonology, it is a natural step within OT that can be expected it to be called for in other cases. More worrisome is the conjectured intrinsic ranking of this constraint family: With its implication that the voicing of a nasal is in itself of more consequence than the voicing of other sonorants (such as vowels), it lacks any obvious grounding in phonetic facts or markedness considerations.

The most serious problem with the SONVOI decomposition analysis, however, is the fact that it leads to unwanted insertion and linkage of [voice] in forms containing a nasal and a **nonadjacent** obstruent, such as *maki* ‘firewood’. Nothing said so far distinguishes such NVC-forms from NC-forms like *tombo* ‘dragonfly’ analysed in section 4, and tableau (44) illustrates how the SONVOI decomposition approach wrongly points to **magi*, with inserted [voice] spread to the medial obstruent, as the optimal output for underlying /maki/.

(44) Wrong candidate selected:

Input: /maki/ ‘firewood’

Candidate	LICENSE	NASVOI	FAITH	VOCVOI
a. !! <small>intended winner:</small> m a k i		*!		**
b. m a k i ↓ V	*!		*	**
c. ✖ <small>wrong winner:</small> m a g i ↓ / V			**	**

Looking beyond such individual examples, the analysis in (44) makes the prediction that nasals cannot cooccur with voiceless obstruents in the same form, a prediction patently wrong not only for Japanese, but in all likelihood also universally. One source of the problem lies in

the fact that the account does not recognize that post-nasal voicing is restricted to strictly adjacent segments, a restriction which seems universal (we know of no cases that cross vowels). What guarantees this kind of locality? Following Kiparsky (1981), Levergood (1984) and Archangeli & Pulleyblank (in press), among others, we posit the constraint in (45) against ‘gapped’ configurations (cf. also the *EMBED constraint in Smolensky 1993).

(45) NOGAP

As the amended tableau (46) shows, the new constraint NOGAP (undominated, and unranked with respect to LICENSE) rules out the previous winner (46c), since a vowel is a potential bearer of [voice]—being a potential bearer is a matter of feature structure, not redundancy. Hence, the correct form (46a) is selected instead. (In order to let the crucial rankings stand out in the tableaux, the conventional dashed lines between the noncrucially ranked constraint columns have been omitted from here on.)

(46)

Input: /maki/ ‘firewood’

Candidate	NOGAP	LICENSE	NASVOI	FAITH	VOCVOI
a. m a k i			*!		**
b. m a k i V		*!		*	**
c. m a k i / V	*!			**	**

However, a consideration of further candidates reveals that NOGAP is not sufficient to solve the excessive voicing problem. Since vowels can bear [voice], there are candidates where spreading proceeds through the vowel, instead of skipping it. This leads straight to another way of wrongly deriving the medially voiced *magi instead of maki shown in (47). Here NOGAP

succeeds in disqualifying (47c), but is powerless against the ungapped but still excessively voiced candidate (47d), which wins over (47a) because of NASVOI.

(47) Wrong candidate selected:

Input: /maki/ 'firewood'

Candidate	NOGAP	LICENSE	NASVOI	FAITH	VOCVOI
a. !! intended winner: m a k i			*!		**
b. m a k i v		*!		*	**
c. m a k i / v	*!			**	**
d. ✗ wrong winner: m a g i // v				***	*
e. m a g i // // v				*****!	

The SONVOI decomposition analysis, besides leading to descriptively incorrect results, also entails erratic (under)specification patterns in surface forms whenever a voiced obstruent is present which can serve as a licensing anchor for [voice]. This is illustrated by forms with an **underlying** voiced obstruent such as *nabe* 'pot' (48).

(48) Questionable result:

Candidate	NOGAP	LICENSE	NASVOI	FAITH	VOCVOI
a. !! intended winner: n a b e v			* !		**
b. ☞ n a b e \ \ v				**	*
c. n a b e \ \ v				*** !	

The voicing specification pattern in (48) can only be described as arbitrary: The winning candidate shows voicing on vowels, but only when they lie on the path between a voice-craving nasal and a voiced obstruent (i.e., where necessary to fulfill both NASVOI and NOGAP). Elsewhere (e.g., for the final vowel in *nabe* (48b)), FAITH prevents voicing on vowels. This last point raises a further disturbing question: Since FAITH is now crucially involved in making the final decision regarding the voicing specifications of vowels, the issue of different degrees of input specification (of redundant values) raises its head again, subverting the results of section 4.

The combined force of these considerations compels us to pursue an alternative approach which shifts the main emphasis in our analysis away from segment-focused voicing constraints towards syntagmatic linkage constraints. The basic idea behind the new approach is the following: NC sequences, in contrast to VC sequences, share voicing not because nasal *voicing* is somehow stronger than vocalic voicing, but because feature *linkage* is less marked in NC sequences than in VC sequences. We will see that this line of analysis enriches our understanding of post-nasal voicing on the one hand, and connects with an interesting line of phonological research on the other.

5.3 NC Linkage

The two problems discussed above—the locality issue, and the confinement of voicing effects to NC clusters—turn out to have one and the same solution. The key lies in the notion, to phrase it informally, that *like things interact*. This idea has been voiced in the literature before (see e.g. Hutcheson 1973, Kiparsky 1988), most clearly in work centering on OCP effects (McCarthy 1986, 1988, Mester 1986, Selkirk 1988, 1993, Padgett 1991, Pierrehumbert 1993). The upshot of this latter work is that dissimilatory effects involving place of articulation are more likely between segments that are alike in other features, notably minor place features and features of stricture or sonority. Work of Selkirk (1988, 1993), Ní Chiosáin & Padgett (1993), McCarthy (1993), and Padgett (1994) finds promise in extending this idea to various assimilatory effects as well.

In this context, let us suppose that linkage of [voice] between nasals and obstruents is less marked than such linkage between liquids/glides/vowels and obstruents, because nasals and obstruents are already more similar in stricture and hence more prone to interact.¹¹ We implement this idea by means of the NOLINK family of constraints in (49)—with the added caveat that the individual constraints should be taken not as irreducible principles, but rather as reflections of a deeper generalization (see the works cited above; the letters V,G,L,N,C in (49) denote vowels, glides, liquids, nasals and obstruents, respectively).

(49) Constraint family: NOLINK

NO-VC-LINK >> NO-GC-LINK >> NO-LC-LINK >> NO-NC-LINK

As conjectured concerning the family of SONVOI constraints discussed earlier (see (41) in section 5.2), this family is ranked intrinsically and universally; this ranking entails the generalization that interaction is less marked between segments more similar in stricture/sonority. Given this decomposition of NOLINK, and the possibility other constraints to intervene between any pair of subconstraints, we propose the following scenario for Japanese:

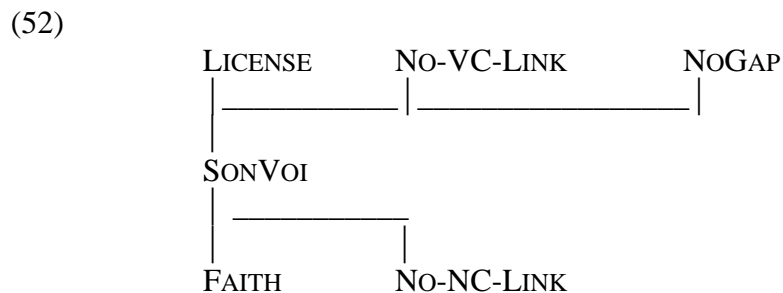

(50) Intervention of SONVOI:

For our purposes, only the separation of NO-NC-LINK from the rest of the family is relevant. As in the discussion of SONVOI decomposition in the previous section, we focus exclusively on the contrast between VC and NC. In these terms, the important subhierarchy of the constraint system of Yamato Japanese is the one in (51).

This correctly entails post-nasal voicing on the one hand, and the failure of other post-sonorant voicings on the other. Combined with the other constraints that play a role in the analysis (NOGAP, LICENSE, and FAITH), we end up with the partial ordering of constraints in (52). For present purposes, we are assuming that NO-VC-LINK is undominated, on a par with LICENSE and NOGAP. (Within the overall grammar of Japanese, NO-VC-LINK is dominated by various constraints—enforcing palatalization and other vowel-consonant interaction effects—that are not relevant here, see Itô & Mester 1994a,b for discussion).

As an illustration of the analysis, consider first the input /šin+te/ ‘dying’ in (53).

(53)

Input: /šin+te/ 'die +
GERUND'

Candidate	LICENSE	NO-VC-LINK	SONVOI	NO-NC-LINK	FAITH
a. š i n t e			***!		
b. š i n t e v	*!		**		*
c.  š i n d e v			**	*	**

Since (53) involves only NC linkage, little has changed from before. The important point is that SONVOI is crucially ranked over NO-NC-LINK; were the opposite ranking correct, our input would surface unchanged as *šinte. Tableau (53) should be compared to (54), where the input form /aki/ containing the VC-sequence /ak/ is shown running the same constraint gauntlet.

(54)

Input: /aki/ 'autumn'

Candidate	LICENSE	NO-VC-LINK	SONVOI	NO-NC-LINK	FAITH
a.  a k i			**		
b. a k i v	*!		*		*
c. a g i v		*!	*		**

As usual, sonorant voicing may arise only if licensed by an obstruent link; hence the quick demise of candidate (54b). Candidate (54c) looks superficially similar to the winning candidate (53c). But linkage of a vowel to an obstruent is precisely what is prohibited by NO-VC-LINK;

unlike NO-NC-LINK, this constraint ranks *above* SONVOI, and so post-vocalic voicing is impossible, eliminating (54c). The remaining candidate (54a), in spite of its two SONVOI violations, is the optimal form. We note for completeness that no evidence here motivates a ranking between FAITH and NO-NC-LINK (we will shortly turn to a consideration of the role of FAITHFULNESS in our analysis).

Recall from the previous section that the SONVOI decomposition analysis suffered from an excessive voicing problem in forms containing both a nasal and an obstruent, whether adjacent or not. We will now show that this NC linkage analysis is free of these problems, and already contains the solution to the locality problem brought up earlier: The very same prohibition on VC linkage which was operative in (54) *aki* also prevents long-distance post-nasal voicing in (55) *maki* 'firewood'. The previously problematic candidate (55d), where voicing spread has swept through the vowel, now crucially violates NO-VC-LINK. The vowel-skipping candidate (55e) continues to violate the constraint against gapped configurations posited above in (45). As desired, the optimal candidate (55a) mirrors the input in not containing any [voice] specification.

(55)

Input: /maki/ 'firewood'

Candidate	NO GAP	LIC- ENSE	NO- VC- LINK	SONVOI	NO-NC- LINK	FAITH
a. m a k i				***		
b. m a k i v		*!		**		*
c. m a k i / v		*!		*		**
d. m a g i // v			*!	*	*	***
e. m a g i / v	*!			**	*	**

Our understanding of the opacity of intervening vowels echoes work stemming from Kiparsky (1981), in which opaque segments are viewed as *non-triggers* of the relevant process. In the present account, however, this behavior is not the result of process-specific stipulations on target and trigger, but rather follows directly from the ranking of quite general and independently motivated markedness conditions.

To sum up the discussion so far: Besides a universal SONVOI constraint, our analysis makes use of a universally ranked NOLINK constraint hierarchy, whose existence is strongly supported by the empirical typology of dissimilation and assimilation patterns across languages. The only relevant 'parameter' to be 'set' within the phonology of Yamato Japanese concerns the ranking of the voicing constraint with respect to the interaction constraint system. Here our analysis inserts SONVOI immediately above NO-NC-LINK within the NOLINK hierarchy. This single move accounts simultaneously for three classes of facts: (i) the presence of post-nasal

voicing, (ii) the absence of other post-sonorant voicing, and (iii) the strictly local character of post-nasal voicing.

It is now a simple matter to answer the other question posed at the outset: Why are there languages without post-nasal voicing? The answer is simply that in such languages, NO-NC-LINK joins other NOLINK conditions in outranking SONVOI—hence SONVOI cannot command the violation of NO-NC-LINK. We illustrate the two possibilities in (56).

(56) Ranking differences between NO-NC-LINK and SONVOI

Ranking	Outcome	Example
SONVOI >> NO-NC-LINK	e.g. /...mp.../ \rightarrow [...mb...]	Yamato Japanese, Zoque
NO-NC-LINK >> SONVOI	e.g. /...mp.../ \rightarrow [...mp...]	Non-Yamato Japanese, English, etc.

More generally, and exploiting the entire hypothesized NOLINK family, we predict the following post-sonorant markedness pattern, derived by ranking SONVOI successively higher in the hierarchy:

(57) Post-sonorant voicing patterns

No post-sonorant voicing	(SONVOI ranked below entire NOLINK hierarchy)
Post-nasal voicing	:
Post-nasal/liquid voicing	:
Post-nasal/liquid/glide voicing	:
Post-sonorant voicing	(SONVOI ranked above entire NOLINK hierarchy)

Whether this hierarchy is correct in all respects (e.g., in its exclusion of post-liquid voicing without post-nasal voicing—barring of course the possible interference of other constraints we are not considering here), remains a domain of future research. However, the work cited earlier on similarity in interaction suggests that markedness predictions like these are on the right track.

With the incorporation of the NOLINK family in our grammar, it becomes important to clarify the relative roles of FAITHFULNESS and NOLINK in our account. Clearly feature FAITHFULNESS is an indispensable element of the overall grammar, NC voicing aside. It is FAITHFULNESS that prohibits unmotivated departures from underlying form in general, preventing e.g. /aki/ from surfacing as *agi by a spontaneous epenthesis [voice] onto the obstruent. Closer to our concerns, it is the ranking of FAITH below SONVOI that allows /šin+te/ ‘dying’ in Japanese to surface as *šinde*—if the ranking were reversed, we would have a grammar without NC voicing, and the outcome would be *šinte*. The low ranking of FAITH in addition ensures that a monomorphemic Japanese form like *tombo* ‘dragon fly’ surfaces with NC voicing *irrespective of the feature (under)specification in the input*, an important result discussed at length in section 4. Turning then to NOLINK, we saw immediately above in (56) that the reranking of the interaction constraint NO-NC-LINK with respect to SONVOI has the same effect for the occurrence of NC voicing. What then are the relative functions of these constraints?

Different from FAITHFULNESS constraints, whose domain is the input-output relation, the NOLINK constraints deal with output wellformedness questions in feature structure—hence their indifference to the *provenance* of feature linkage (underlying or inserted). This difference is less obvious than other traits of NOLINK we have focussed upon, e.g. its role in barring post-vocalic voicing or non-local post-nasal voicing, effects that FAITH alone does not speak to in any case.

The main result of our analysis for the relative ranking of FAITHFULNESS with respect to NO-VC-LINK is the following: NO-VC-LINK >> SONVOI (55a/d); SONVOI >> FAITH (53c/a). Hence by transitivity NO-VC-LINK >> FAITH. This derived ranking is of significance for cases where NOLINK and FAITHFULNESS conflict. Continuing the lexicon optimization investigation of section 4, let us consider two candidate inputs for the form *ude* ‘arm’, one with sparse [voice] specifications (58a), and one with fully linked [voice] (58b).

(58) a. /u d e/ b. /u d e/
 | \ | /
 v v

For input (58a), NO-VC-LINK and FAITH agree on an output with [voice] linked only to /d/, not to vowels. Yet this parallelism between FAITH and NOLINK vanishes with a shift in underlying form to the fully linked representation in (58b). Here the two constraints are in inevitable

conflict: Whereas NO-VC-LINK militates against any such links, whether inherited from the input or acquired through Gen, FAITH insists on the preservation of underlying structure. As it happens, direct empirical evidence from e.g. Rendaku cannot bear on the correct surface form in this case.

Our analysis resolves this issue in favor of the underspecified output structure: Given the ranking of NO-VC-LINK over FAITH, the grammar will select the candidate showing better linkage behavior, irrespective of the amount of linkage specified in the input. As a result, the selected output has no [voice] specification on vowels. This is shown in (59) for the sparsely specified input (58a), and in (60) for the fully linked input (58b).

(59)

	Candidate	NO-VC-LINK	FAITH
a.	u d e v		
b.	u d e \\ / v	* ! *	* *

(60)

	Candidate	NO-VC-LINK	FAITH
a.	u d e \\ / v		* *
b.	u d e \\ / v	* ! *	

Reinterpreting this convergence of parsed output structures as determining lexically optimal inputs, the tableau-des-tableaux scheme of section 4, applied to (59) and (60), settles matters in favor of (58a) as the real input, as shown in (61).

(61)

	Input	Output	NO-VC-LINK	FAITH
a. 	u d e v	 u d e v		
b.	u d e \ / v	 u d e \ / v		* ! *

6 Conclusion: Summary and Outlook

Recapitulating our main proposals in this paper, we first turn to the three-level hierarchy of constraints repeated in (62).

(62) Overall ranking of constraints:

In terms of the conflict-based ranking logic of Optimality Theory, the constraint system in (62) has a straightforward set-up: Between a top layer consisting of the undominated (and in our analysis unviolated) constraints LICENSE, NO-VC-LINK, and NOGAP and a bottom layer consisting of the dominated (and frequently violated) constraints FAITH and NO-NC-LINK, we find the segment markedness constraint SONVOI. This simple ranking scenario is responsible for the intricate specification/underspecification behavior of voicing in Japanese: Besides solving the voicing paradox, it accounts for the appearance of NC voicing, for the locality of the interaction, and for the absence of other postsonorant voicing in Japanese. And at the level of typology, the freedom of individual grammars to rerank SONVOI with respect to the substantively fixed

hierarchy of NO-LINK constraints imposes plausible limits on the crosslinguistic variation space for voicing interactions.

Compared to earlier work, the analysis presented here constitutes a significant step towards a principle-based theory, eliminating rule stipulations. The six constraints in (62) are all independently motivated and arguably universal—if not in the exact formulation proposed here, then at least in spirit. As substantive elements of phonological theory, they are particular members of the constraint families shown in (63) governing input/output relations, enforcing domain connectedness (together with other contiguity effects), regulating feature licensing, and controlling the markedness of segments and segmental links.

(63) Substantive typology of constraints

Constraint Families				
Input/Output Disparity ("FAITH")	intrinsically ranked:		Licensing	Domain Connectedness
	Segment Markedness	Linkage Markedness		
PARSEFEAT FILLFEAT PARSELINK FILLLINK	SONVOI	NO-VC-LINK NO-NC-LINK	LICENSE(VOI)	NOGAP

Taken as a whole, the analysis provides strong support for the basic tenets of Optimality Theory, as developed in PS 1993: Grammatical constraints are ranked and violable, and there is no serial derivation. One could envision an account of Japanese in a serial phonology invoking constraint violation and repair. For example, we might say that the redundancy rule [nasal]→[voice], applying early, targets all nasals, violating a constraint against redundant feature specification. These violations could then be repaired, where possible: spreading to a neighboring obstruent grants licensing; otherwise, [voice] must delink again. As PS 1993 point out, such repair and rescue scenarios have the ‘do α , except when β —unless γ ’ quality signalling a hidden appeal to ranking and violability, the very factors that are elevated to the level of principle in

Optimality Theory. In other words, such analyses would merely replicate the optimality-theoretic account in a stipulative and inexplicit way.

As far as conventional underspecification theory is concerned, it is replaced in our proposal by a theory of feature licensing which builds on earlier work on licensing (e.g. Itô 1986, Goldsmith 1990, Lombardi 1991, Itô & Mester 1993) and marking conditions (Kiparsky 1985, Padgett 1991, 56–58) (see also Steriade 1994 for an independently developed concept of ‘indirect licensing’). Redundant feature specification is governed by a family of licensing constraints—LICENSE(Φ)—and not by the more familiar marking/feature cooccurrence conditions. Our work thus militates against the use of feature cooccurrence restrictions like *[+son, +voice] to ensure underspecification, since they imply a simple incompatibility between the relevant features. As we have seen, there is no such incompatibility; rather, there is only a failure of licensing. Only this notion of licensing can illuminate the free occurrence of redundant features in doubly linked structures. We are of course not arguing against feature cooccurrence restrictions in general, which are needed to rule out cooccurrences of *antagonistic* features, such as *[+son,–voice] (or, in a theory with privative [voice], *[+son,+spread glottis], see Mester & Itô 1989, Lombardi 1991). Antagonistic feature cooccurrence restrictions are independent of Licensing Theory (for example, there is no sense in which double linking renders voicelessness in sonorants wellformed) and play an important role in constraining the derivation of segments by assimilation, see Kiparsky (1985), Pulleyblank (1989), Cohn (1989), Archangeli & Pulleyblank (in press), Padgett (1991:48–63, to appear).

In another vein, we note the possible implications of our results for a broader conception of underspecification. The program developed here for redundant features might be profitably extended to include an investigation of the specificational behavior of *unmarked* (but not redundant) values of contrastive features, thereby addressing the perennial topic of degree of underspecification—full, contrastive or radical. Thus, we anticipate that the opposing contrastive and radical viewpoints may reveal themselves as reifications of two different orderings of antagonistic constraints. As an example, consider the place feature [coronal], perhaps the best-investigated case in point (see Paradis & Prunet 1991 and references therein). We might attribute [coronal] behavior to a conflict between some kind of licensing constraint on the one hand (cf.

*PL/COR in PS 1993, 181, and Kiparsky 1994), and constraints against empty Place nodes and unparsed features on the other hand (FILLPLACE, PARSEFEATURE, *ibid.*). If such an approach proves fruitful, the contrast between ‘radical’ and ‘contrastive’ views of underspecification reduces to a contrast in ranking, with empirical consequences to be pursued. In a similar vein, redundant feature specification is determined in our view by a conflict between licensing constraints militating against the presence of redundant features and constraints requiring the presence of those very same features. The ranking of these (families of) constraints with respect to each other tips the scales either in favor of specification, or of underspecification.

Finally, let us return one last time to the issue of redundant feature underspecification in outputs. Future investigations will have to devote serious thought to proposals (as in Steriade 1994) that allow the phonology direct access to a vast range of phonetic properties, and in this way are able to make use of a multitude of distinctions in phonological descriptions that are not available within the limited feature set of Jakobsonian phonology. There is no doubt that careful attention must be paid to the phonetic interpretation of phonological representations. However, it seems to us that a direct importation of acoustic, physiological, and aerodynamic factors into phonology, while making certain generalizations more easily statable (like any expansion of the descriptive vocabulary), might lead to a loss of explanation.¹² Proposals reviving the idea of “phonological projections” (Halle & Vergnaud 1978) in the form of rule-specific visibility parametrization have little trouble in making fully specified phonological representations compatible with the facts by declaring, for certain processes, that only marked, or only contrastive, features may be accessed (Calabrese 1994)—a descriptive success bought at the price of rule-by-rule stipulations, thereby implicitly or explicitly giving up on the search for more fundamental phonological principles.¹³

While the particular facts discussed throughout this paper are specific to Japanese, our approach to redundant feature (under)specification is based on a general theory of feature markedness and licensing applies to a broad class of other cases. Facts like those of NC voicing have not generally informed the discussion of underspecification in the literature. This is partly due to the difficulty in identifying such facts, and not to their rarity (for features different from voicing, we refer the reader to the brief analysis of Turkish rounding effects presented in Itô, Mester, & Padgett (1993, 18–28) and the more fully developed treatment in Ní Chiosáin &

Padgett 1993). We have chosen Yamato Japanese as a testing ground for our licensing-based theory of feature specification, with its entailment of underspecification as an emergent output property, because it is particularly suited for the empirical investigation of phonological voicing—the morphophonemic process of Rendaku allows access to information about phonological specification and underspecification which is not usually available in other languages.

Observations about Japanese voicing specifications, like all observations, are ultimately theory-bound—here they are molded by the autosegmental/OCP-based view of Rendaku, Lyman's Law, and Voicing Spread in Itô & Mester (1986), itself predicated on the fundamental assumption that phonological representations are redundancy-free. Within optimality-theoretic approaches championing full specification (see e.g. Smolensky 1993 for a step in this direction), the project of capturing the central phonological properties of Japanese voicing strictly in markedness terms has remained so far elusive, but is clearly worth pursuing—we await competitive alternatives which are able to match the underspecification-based account in terms of elegance and depth of explanation.

Notes

. This work was supported in part by faculty research grants funded by the University of California at Santa Cruz to each of the three authors. Earlier versions of this paper were presented at *Trilateral Phonology Weekend I*, *Rutgers Optimality Workshop I*, *Osaka Phonology Workshop*, and in seminars at UMass/Amherst and UC/Santa Cruz. We would like to thank the participants at these occasions, as well as the two LI readers, for stimulating questions and helpful suggestions. For detailed comments on an earlier version, we are grateful to Eric Baković, Stuart Davis, Bruce Hayes, Sharon Inkelas, John Kingston, Orhan Orgun, Lisa Selkirk, Joe Stemberger, Donca Steriade, Moira Yip, and Cheryl Zoll. Special thanks are due to John McCarthy, Máire Ní Chiosáin, Alan Prince, and Paul Smolensky for significant help at various points in our relentless, but always unfulfilled, pursuit of perfection.

1. The morphosyntactic distribution of the voicing morpheme is an entirely separate issue: besides morpheme class (Yamato vs. non-Yamato), the argument structure of the whole compound plays a decisive role in this context, see Uribe-Etxebarria 1992 for recent discussion.
2. Clusters of the form $\{w/r\}+C$ are syllable-structurally impossible in Japanese, but they do arise underlyingly in the verbal morphology, as shown in (8b,c).
3. It is conceivable that these restrictions on \gg should be loosened in some respects (e.g., from a total to a partial order), see PS 1993 for discussion.
4. As PS 1993:197-198 note, this kind of infinity is no great liability; a theory of grammar requires that the notion 'best-satisfactor' be well-defined, and *not* that it be constrained by a priori notions of computability. Furthermore, the sources of infinity are few in number (mainly epenthesis, the insertion of non-underlying material) and can be controlled by a suitable heuristic.
5. Given the presence of redundant specifications in the phonetic output, e.g. voicing of [m] in *kami*, any account of Japanese necessarily distinguishes the phonological and phonetic levels. Pursuing this point, we might suppose that phonetics differs from phonology in that LICENSE is lower on the constraint hierarchy in the former. While such statements capture an intuition about the phonology/phonetics distinction, it remains to be seen whether it is reasonable to employ the

vocabulary of OT itself with reference to phonetics.

6. Here we follow PS 1993 in assuming that no element may be literally removed from the input: i.e., the generator fulfills the condition that inputs are literally contained in all associated outputs (a monotonicity requirement dubbed "Containment" in McCarthy & Prince 1993:20). Hence the notion 'failure to parse', in contrast to removal, of an element. There are a number of alternative possibilities for encoding input-output relations in Optimality Theory (see for example Itô, Mester, & Padgett 1993), Containment is only one of the available options. (See McCarthy & Prince 1994b for an explicit alternative theory using a correspondence relation holding between each output candidate and the input). As far as we can see, little, if anything, of the substance of our analysis and theory depends on the precise method of encoding input/output disparities, and we have here adopted the standard Containment view for ease of exposition.

7. See also McCarthy 1993 for a somewhat different theory appealing directly to morphemic affiliation (MSEG).

8. For any FILLFEAT violation associated with a single FILLLINK violation (and similarly, for any PARSEFEAT violation associated with a single PARSELINK violation), we have adopted the policy of including only one mark in the FAITH column (see e.g. (27bc) and (28a)). Besides expository convenience, this practice avoids an unwarranted reification of association lines (cf. also the features-as-attributes view ascribed to J. Pierrehumbert in McCarthy & Prince 1994b). The point of the FAITH-LINK constraints, as separate from FAITH-FEAT, is to militate against the establishment (or nonparsing) of *additional multiple* associations, see for example (31c) below. In its focus on spreading configurations, it corresponds to the *SPREAD constraint of Itô, Mester & Padgett 1993.

9. It goes without saying that underlying representations by themselves continue to be crucial in determining the class of surface representations generated by an optimality-theoretic grammar for a given language: unpredictable lexical information is by definition irreducible.

10. For syllable-structure reasons, other sonorants consonants besides nasals cannot precede obstruents in the output. When such clusters arise in input forms through morpheme concatenation, they are reparsed as geminates: /kaw+te/ → *katte* 'buying', /tor+te/ → *totte* 'taking', etc., without any trace of voicing.

11. It is perhaps significant that only NC clusters share place features also. But the notion that "like things interact" cannot be interpreted to mean simply that segments already sharing feature linkage are more likely to share more—the similarity (e.g. in stricture or sonority) need not involve linkage (see Padgett 1991 and Pierrehumbert 1993). The last point further indicates that the similarity idea cannot be fully geometrized, either by class nodes representations (Clements 1985—see Padgett 1994 for discussion) or by means of dependency-theoretic structures (Mester 1986, Selkirk 1988; see Itô & Mester 1994b).

12. For example, it has been proposed that voiced obstruents can be distinguished from voiced sonorants by referring to the aerodynamic fact that the production of the former, but not the latter, goes regularly hand in hand with an expansion of the pharynx (see Steriade 1994, and the development in Pater 1994). But this does not take into account, as John Kingston (personal communication) reminds us, that the production of voicing on the obstruent portion of intervocalic NC clusters—i.e., precisely the clusters under discussion in this paper—involves little expansion of the pharynx, if any (since the oral stop portion is of extremely short duration). If so, a reference to “expanded pharynx” in this context amounts to a phonological diacritic for obstruent voicing.

13. Consider, for example, the set of grammars that would result from the free permutation of visibility clearances among the phonological rules posited in Calabrese's (1994) restatement of Itô, Mester, & Padgett's (1993) optimality-theoretic analysis of voicing in Japanese.
